ABSTRACT

We estimate the expected distribution of displacements between the two dominant dark matter peaks in halos within a mass range corresponding to galaxy groups. We find that 5% to 25% of the dark matter systems with circular velocities in the range 300 km s^{-1} to 700 km s^{-1} show multimodal morphologies with displacements between the dark matter clumps equal or larger to $\sim 400h^{-1}\text{kpc}$, which corresponds to the observational constraint the object SL2S J08544-0121 located at $z = 0.35$.

Subject headings: cosmology: theory – dark matter

1. INTRODUCTION

The Bullet Cluster provided a new kind of observational evidence of the existence of dark matter. Quantifying the displacement between dark matter and the dominant baryonic component (hot X-ray emitting gas) (Forero-Romero et al. 2010) has been used to test the CDM paradigm itself by quantifying the substructure velocity required to produce such displacement (Hayashi & White 2006) to finally estimate the expected abundance of such events in the Universe.

Since that time there are other observations of other Bullet-like systems [...].

Recently (Gastaldello et al. 2014) observed baryonic-DM displacement of $124 \pm 20 \text{ kpc}$ in a group-like system with a total mass $2.4 \pm 0.6 \times 10^{14} M_{\odot}$. Systems of this mass are ~ 10 times more massive than cluster systems in the mass range $> 10^{15} h^{-1} M_{\odot}$, this opens up the possibility of observationally finding bullet groups in a fair amount to impose constraints on Λ CDM. This greater abundance has to be weighted by the fraction of systems that present large displacements. Such study has been performed for clusters but not for lower mass systems.

In this Letter we present prediction for the abundance of group-like systems that might show a DM-baryon displacement. To this end we use a N-body cosmological simulation with such a resolution that allows us to identify multimodal dark matter clumps in the circular velocity range $300 - 700 \text{ km s}^{-1}$.

This paper is organized as the follows. In Section 2 we present the simulation and the halo catalogs used in this work. We continue in Section 3 with the geometry of the problem at hand and the measurements setup. Next in Section 4 we present our results to finish with a discussion and conclusion in Sections ?? and ??.

2. SIMULATION, HALO CATALOGS AND PAIRS

We use the Bolshoi Run, a cosmological DM only simulation over a cubic volume of $250 \text{ comoving } h^{-1} \text{ Mpc}$ on a side. The simulation uses the ART code to follow the evolution of a dark matter density field sampled with 2024^3 from $z = 80$ to $z = 0$ [...]. The cosmology used corresponds to the spatially flat concordance model with the following parameters: the density parameter for

matter (dark matter+baryons) $\Omega_m = 0.27$, the density parameter for baryonic matter $\Omega_b = 0.0469$, the density parameter for dark energy $\Omega_{\Lambda} = 0.73$, the Hubble parameter $h = 0.7$, the normalization of the Power spectrum $n = 0.95$ and the amplitude of mass density fluctuation (at redshift $z=0$) $\sigma_8 = 0.82$. The number of particles used for each of the DM component was 2048^3 , resulting in a mass resolution of $1.35 \times 10^8 M_{\odot} h^{-1}$. Klypin et al. (2011).

We use halo catalogs constructed using the BDM algorithm. [...] (Riebe et al. 2013).

In the snapshots at redshift $z = 0.0, 0.25, 0.5$ and 1.0 there are XX, XX, XX, XX host halos with circular velocities $V_c > 300 \text{ km s}^{-1}$ and XX, XX, XX, XX sub-halos with circular velocities $V_c > 75 \text{ km s}^{-1}$. These two sets of halos constitute the basis for our analysis.

For each host halo in the sample we find its most massive sub-halo. Each pair host/sub-halo is considered as a potential Bullet Group and is kept for the measurement and analysis described in the next section.

3. BULLET GEOMETRY AND MEASUREMENT SETUP

The Bullet groups is composed by two halos. the host halo and the sub halo. This configuration is described by the position and velocity of the sub-halo in a frame of reference where the main halo is at rest; thus $\vec{v} = \vec{v}_{sub} - \vec{v}_{halo}$ and $\vec{r} = \vec{r}_{sub} - \vec{r}_{halo}$, where the subscripts *host* and *sub* refer to the host and sub-halo in the frame of reference of the simulation, respectively.

The angle between these two vectors characterized by,

$$\mu \equiv \cos(\theta) = \frac{\vec{v} \cdot \vec{r}}{\|\vec{v}\| \|\vec{r}\|} \quad (1)$$

encodes the geometry of the collision, i.e. cases of $|\mu| \approx 1$ can be considered as head-on collisions while $|\mu| \approx 0$ describe a grazing trajectory.

The bullet-like encounter can be instantaneously described by quantities the following quantities the circular velocity of the host and the sub-halo, $V_{c,host}$ and $V_{c,sub}$; the size of the host halo R_{vir} ; the relative position and velocity of the substructure, \vec{v} and \vec{r} ; and the angle between the position and velocity μ .

As a first approximation there are two quantities that

are available from observations of these Bullet-like systems. The projected distance between two dominant dark matter clumps and the ratio of the galaxies luminosities associated to them. From the simulation point of view this can be translated into the 2D projected values of $||\vec{r}||$, its value relative to the virial radius $D_{\text{off}} = ||\vec{r}||_{2D}/R_{\text{vir}}$ and the ratio of the circular velocities of the two clumps $V_{\text{c,sub}}/V_{\text{c,host}}$. In a higher degree of detail, in order to gain better insight we use the sub-structure velocity as a fraction of the host's circular velocity, $||\vec{r}||/V_{\text{c,host}}$, as a measure of the strength of the interaction. Finally, we also measure the geometry of each interaction through the values for μ .

All the physical quantities described above can be used to describe the three main stages in a bullet-like encounter. First, the sub-halo crosses the virial radius of the host halo starting a head on collision, $||\vec{r}||/R_{\text{vir}} \approx 1$ and $\mu \approx < 0.0$. Second, as the sub-halo crosses for the first time the center of the host halo $||\vec{r}||/R_{\text{vir}} < 1.0$ and $\mu > 0.0$. Third, as the sub-halo reaches apogee and comes back to the center of the halo $||\vec{r}||/R_{\text{vir}} < 1.0$ and $\mu < 0.0$. We use this quantities in Section XXX to fully characterize the different kind of interactions observed in the Bolshoi simulation.

4. RESULTS

4.1. Displacements and Relative Circular Velocities

The main result of this paper is summarized in Figure 1, it presents the integrated probability distribution for the displacement between the center of the host halo and its dominant sub-halo. The left panel shows the displacement in physical units and the right panel as a fraction of the virial radius of the host halo.

Figure 1 shows the results for two different populations; groups with $300 \text{ km s}^{-1} < V_{\text{c,host}} < 700 \text{ km s}^{-1}$ and clusters with $V_{\text{c,host}} > 700 \text{ km s}^{-1}$. Additionally, this is presented for all redshifts $z = 0.0, 0.25, 0.5$ and 1.0 .

The panel with the physical displacements also shows a vertical stripe with the estimated displacement for the Bullet-group reported by Gastaldello et al. (2014). Considering this system as consistent with the groups sample we see that a fraction of $\sim 15 \pm 2\%$ of the groups should present a displacement equal or larger than the one estimated for SL2S J08544-0121, this fraction is close to $45 \pm 2\%$. The panel with the normalized displacements shows a distribution that can be considered close to universal in the sense that the two samples (groups and clusters) at all redshifts present a similar trend.[...]

Figure 2 shows 2D histograms in a plane composed by the ratio of the two circular velocities $V_{\text{c,sub}}/V_{\text{c,host}}$ and the physical displacements. This is revealing because these two quantities can be constrained by observations. The displacement is a direct observable, while the ratio of the circular velocities can be estimated from lensing studies or approximated by the ratio of the total galaxy luminosity associated with the galaxy peaks.

To construct this figure we co-add all the halos in the sample (left, groups; right, clusters) at all redshifts. We stack the data because we do not observe any strong time evolution, additionally this allows us to increase the signal in each bin. Overplotted there is an circle with error bars that represents the observational estimates for the

system SL2S J08544-0121 using the fraction in velocity dispersion in the line-of-sight of the group SL2S SJ08544-0121 ($\sigma_{\text{host}} = 341^{+43}_{-109} \text{ km s}^{-1}$ and $\sigma_{\text{sub}} = 185^{+30}_{-62} \text{ km s}^{-1}$) reported by Muñoz et al. (2013) and the DM displacement inferred from the data presented by Gastaldello et al. (2014).

4.2. Relative Velocities

In Figure 3 we present the integrated probability of the relative peculiar velocities of the sub-halos with respect to the host halo. The left panel presents this velocity in physical units while the right panel presents them as a fraction of the circular velocity of the host halo.

The panel with the normalized velocities shows that the distribution of sub-halo velocities is close to universal. Regardless of the mass of the host halo and the redshift the integrated distributions lie very close to each other.

The median of this distribution is located at $v/V_{\text{c,host}} = 1.1$. We also note the strong break at $v/V_{\text{c,host}} = 3.0$ that is present in the data from the group sample that allows us to probe fractions on the order of 10^{-4} . This break is located close the escape velocity of $v/V_{\text{c,host}}$ for dark matter halos following a NFW profile with a concentration value $c \approx 6$ (Hayashi & White 2006).

4.3. Collision Geometries

Figure ?? presents the geometry of the bullet groups using the variables μ and D_{off} . The first evident feature is that most of the configurations have $|mu| > 0.9$ ($\theta \leq 30^\circ$), meaning that most of the collisions can be described as a head-on while only a minority with $|mu| < 0.9$ have more tangential trajectories. For the pairs on radial trajectories there are three regions of interest in this plane that describe different stages in the collision, assuming that the sub-halo merges or falls below the detection threshold after the first pass through the center of the host halo.

The first region has $\mu \approx -1$ and $D_{\text{off}} > 0.6$, which locates the systems where a head-on collision has just started. The sub-halo is close to the boundary of the host halo and is infalling. The second region has $\mu \approx 1$ and $D_{\text{off}} < 0.6$; at this stage the collision continues after the first crossing of the host's center, the low number of halos with radial infalling velocities and displacements $D_{\text{off}} > 0.6$ suggest that this is the maximum range of radii for the apogee. The third region corresponds to $\mu \approx -1$ and $D_{\text{off}} < 0.6$ which corresponds to the secondary infall after apogee.

4.4. Displacement between Dark Matter and Baryons

These different collision geometries will produce different results in terms of the displacement between dark matter and baryons. Strictly speaking, the results we have derived so far, apply to multimodal groups and their expected separation between the two dominant dark matter clumps but it should not be interpreted that all have a corresponding DM-baryon displacement. The systems where the halo is starting to fall into the host ($\mu \approx -1$, $D_{\text{off}} > 0.6$) should not present a detectable DM-baryon displacement.

We clearly expect such displacement in the case where the sub-structure has already passed through the center

FIG. 1.— Integrated probability distribution for the displacement between the host halo and its dominant sub-halo. The left panel shows the results in terms of the physical displacements and the right panel the same displacement normalized by the virial radius of the host halo. The continuous line corresponds to the halos in the group sample $V_{\text{circ,host}} > 700 \text{ km s}^{-1}$ and the dashed lines to the sample $V_{\text{circ,host}} < 700 \text{ km s}^{-1}$. The vertical stripe corresponds to the estimate of the separation between the two dark matter clumps in the results reported by Gastaldello et al. (2014) for the group SL2S J08544-0121. The right panel shows the same results normalized by the virial radius of the host halo.

FIG. 2.— 2D histogram in the plane $V_{\text{c,sub}}/V_{\text{c,host}} - d_{2D}$. The left panel corresponds to groups and the right panel to clusters. The circle with error bars corresponds to SL2S J08544-0121 data reported from Muñoz et al. (2013) and Gastaldello et al. (2014). The data used to construct the histograms integrates the objects at all redshifts.

of the host halo. In this section we attempt an estimation for the DM-baryon displacement statistics. We work under the following hypothesis. First, we consider that systems with $|\mu| < 0.9$ have a baryonic displacement, d_{2D}^{bar} , equal to zero. Second, we consider that all systems with infalling velocities $\mu < -0.9$ and large displacements $D_{\text{off}} > 0.6$ also have baryonic displacements equal to zero. Third, for all the other cases we estimate the displacement between the baryons and the dominant DM peak by the distances between the dominant peak and the center of mass of the main halo, $d_{2D}^{\text{bar}} = D_{\text{off}} R_{\text{vir}}$, where X_{off} is the offset computed for each host halo in the original catalog.

This simplified model does not take into account that there is a fraction of halos with $\mu < -0.9$ and $D_{\text{off}} < 0.6$ for which the collision has not started and should have

$d_{2D}^{\text{bar}} = 0$. A detailed modeling of this fraction requires the study of the complete merger tree of the halo and sub-halo, a study beyond the scope of this Letter. Instead we caution the reader that the derived fraction of halos with a displacement $< d_{2D}^{\text{bar}}$ can be considered as an upper limit.

The results for the integrated distributions for $> d_{2D}^{\text{bar}}$ are shown in Figure 5.[.]

In order to facilitate the reproducibility and reuse of our results we have made available all the data and the source code available in a public repository. [...]

5. CONCLUSIONS

In this Letter we estimate fraction of galaxy groups that can present observational features associated to a bullet-like event. This is motivated by the recent ob-

FIG. 3.— Integrated probability distribution for the relative velocity of the sub-halo with respect to its host. The left panel shows the results in physical units while the right panel show the same values normalized by the circular velocity of the host halo. The line coding follows the same structure as Figure 1

FIG. 5.— Integrated probability distribution for the estimated baryonic displacements in the group and cluster samples at all redshifts.

servational results of (Gastaldello et al. 2014) where

a system (SL2S J08544-0121) on the mass range $1 \times 10^{14} h^{-1} M_{\odot}$ and velocity dispersion 650 km s^{-1} was reported to feature a displacement between its baryonic (hot gas) and dark matter components.

Our estimate is based on large N-body DM-only cosmological simulation. We estimate the distribution of projected displacements between the dominant DM clumps in two kinds of systems; groups with circular velocities $300 \text{ km s}^{-1} < V_c < 700 \text{ km s}^{-1}$ and clusters with $V_c > 700 \text{ km s}^{-1}$. We report these results at four different redshifts $z = 0.0, 0.25, 0.5$ and 1.0 .

We find that a fraction of $XX \pm XX\%$ of the halos in the group sample can present a displacement equal or larger than the observed displacement for SL2S J08544-0121. We also present these results in terms of the ratio of the circular velocities of the sub-halo to the host halo to find that the system SL2S J08544-0121 is found within the expected parameter space spanned by the simulation.

Next we describe the geometry of the collision by the angle between the position and velocity vectors of the

sub-halo with respect to the host. This allows us to separate three different instances: the sub-halo crosses the virial radio of the host, the sub-halo goes through the center of the host and the secondary infall after reaching apogee.

From this analysis we estimate a the integrated distribution of the displacements between the DM and the baryonic component. In this case we find that a fraction of $XX \pm XX\%$ halos in the group sample should present displacements equal or larger than those observed for the Bullet-Group SL2S J08544-0121.

The results we present here can be used as a potential test of Λ CDM. (Comments about Gaels results on multimodal groups).

The CosmoSim database used in this paper is a service by the Leibniz-Institute for Astrophysics Potsdam (AIP). The BolshoiP simulation was performed within the Bolshoi project of the University of California High-Performance AstroComputing Center (UC-HIPACC) and was run at the NASA Ames Research Center.
